1. Ministry of Education Key Laboratory for Cross-Scale Micro and Nano Manufacturing, Changchun University of Science and Technology, Changchun 130022, China.

The solid-liquid two-phase abrasive flow precision machining technology is widely used in aerospace, precision machinery, automotive industry and other fields, and is an advanced manufacturing technology that effectively improves the inner surface quality of workpieces. In this paper, the fifth-order variable-diameter pipe parts are taken as the research object. By discussing the collision between the abrasive particles and the wall surface, it is revealed that the material removal of the workpiece is caused by plastic deformation, and then the mechanism of precision machining of the abrasive flow is clarified. Through numerical analysis and experimental research, it is found that the incident angle can affect the precision machining quality of the abrasive flow. When the inlet velocity of the abrasive flow is 45m/s and the incident angle is 15°, the fifth-order variable-diameter pipe can obtain the most good surface quality. Abrasive flow machining improves the surface quality of small holes better than that of large holes. In order to obtain uniform surface quality, it is necessary to use two-way machining to perform abrasive flow machining. The surface texture of the fifth-order variable-diameter pipe workpiece after precision machining by abrasive flow becomes clear and smooth, and the surface quality is obviously improved. The research results can provide theoretical guidance and technical support for the popularization and application of solid-liquid two-phase abrasive flow precision machining technology, with important academic value and application value.

Keywords: Abrasive flow precision machining; Numerical analysis; Variable-diameter pipe; Quality control

Highlights:

⚫ The CFD-DEM coupling theory and the removal mechanism of abrasive flow polishing materials were analyzed.

⚫ The surface quality of the fifth-order variable-diameter tube after polishing by abrasive particle flow was discussed from different inlet speeds and incident angles.

⚫ Through numerical simulation, the optimal process parameters for polishing the fifth-order variable caliber tube with abrasive flow were obtained.

⚫ Experiments using abrasive particle flow to polish a fifth-order variable-caliber tube have verified the validity and reliability of the numerical analysis.

1. Introduction

With the rapid development of engineering technology, machining has begun to move from rough
machining to precision and ultra-precision machining, and abrasive particle flow polishing is a precision machining technology in the field of ultra-precision machining. During the abrasive flow polishing process, the abrasive is a mixture of abrasive particles and fluids, and flows through the inner hole channel or curved surface at a certain inlet speed [1-3]. The basic working principle of abrasive particle flow is to squeeze the abrasive fluid with special rheological characteristics to make it flow through the closed flow channel constrained by the fixture and the workpiece. Realize precision machining under the action of micro cutting to obtain the inner surface of the part with high precision [4-6]. As abrasive tools, the abrasive particles continuously collide with the surface to be processed, and finally achieve the purpose of polishing the surface to be processed. Abrasive is the most important processing medium in the process of abrasive flow polishing, and it is also the main factor controlling the polishing effect [7-9]. For the study of flow field, numerical simulation method is generally used. The traditional finite element software (Computational Fluid Dynamics (CFD)) has certain limitations. The velocity of fluid at the wall surface is zero by default, and the solid phase abrasive particles are mostly calculated by pseudo-fluid in the two-phase flow, so the velocity of the abrasive particles impacting the wall surface is also zero [10-12]. In the actual processing, the abrasive particles enter the fluid boundary layer and maintain the original motion state under the action of inertia, and then impact the wall surface to produce cutting effect [13-15]. Discrete element method simulation of abrasive flow polishing process mainly refers to simulating the flow state of abrasive particles in the workpiece cavity, analyze the dynamic parameters between the abrasive particles and between the abrasive particles and the workpiece, so as to realize the quantitative and numerical analysis of the machining process [16-18].

Because abrasive flow precision machining technology can effectively deburr, polish and round the workpiece, the workpiece can obtain higher precision, and a large number of domestic and foreign scholars have conducted in-depth research on it [19-21]. Mohanty R and other scholars used the DEM-CFD method to predict the flow behavior of packed beds. Random filling was performed using DEM technology, and the flow of the packed bed was studied by a single-phase laminar flow model. The flow follows an oscillation mode with a similar radial voidage. The experimental results show that DEM and CFD simulations can predict the flow behavior in packed beds [22]. Kim KJ and other scholars studied the effects of various abrasive flow machining process parameters are investigated for holes intersecting at right angle with offset. Through the use of L8 (2^7) orthogonal array to experimentally study the flow distance, abrasive particle size, abrasive concentration, abrasive viscosity and flow velocity of AL6061 specimens, The results show that the flow distance has the greatest effect on the removal of burrs, and the flow velocity has the least effect on the removal of burrs [23]. Li Junye and other researchers have used the mesoscopic scale of particles as a research object in the molecular dynamics theory, combined with hydrodynamics, to carry out the numerical simulations. They analyzed the collision between abrasive particles and wall surface, studied polishing temperature and different cutting angles of the abrasive flow precision machining. Moreover, they also compared their work with experimental data. Their results show that optimal temperature range between abrasive particle and wall collision processing is 300K-310K; The small cutting angles can improve the surface quality and reduce the inside defects of the workpiece [24]. In the ultra-precision machining process, the economics and sustainability of production also need to be considered. Tan RK and other scholars have adopted the new machining technology of Ultrasonic Elliptical Vibration Assisted Cutting (UEVC) to solve the processing difficulties of Ti-6Al-4V alloy in dry ultra-precision cutting (TDUC) process. It not only improves the surface quality of the workpiece but also provides a sustainable process [25].
Chetan and other scholars compared the technology of low temperature cooling and low temperature treatment with the cooling method of MQL based on Al2O3 nanoparticles during the turning of nickel-based Nimonic 90 alloy. Based on the degree of wear of the tool face and the machining quality of the workpiece surface, it was concluded that a low temperature cooling environment is the best way to process Nimonic 90 alloy [26].

Based on discrete element theory and method, this paper constructs a numerical analysis model of solid-liquid two-phase flow of fifth-order variable-diameter pipe parts, and performs numerical simulation analysis under CFD-DEM coupled field conditions to discuss the influence of coupling field such as fluid dynamic pressure and total abrasive energy on the polishing quality of fifth-order variable-diameter pipe. The experiments of abrasive flow precision machining were carried out, and the surface quality of the inner surface before and after polishing is compared and analyzed to study the surface quality effect of the abrasive flow precision machining of the variable diameter pipe parts. The research results can provide theoretical guidance and technical support for the popularization and application of solid-liquid two-phase abrasive flow precision machining technology.

2. Study on Material Removal Mechanism of Abrasive Flow Precision Machining

In order to study the effect of abrasive particles on the wall surface of the fifth-order variable-diameter pipe in the process of abrasive flow precision machining, it is necessary to visually calculate and analyze the movement process of the abrasive particles in the workpiece. In the process of abrasive flow precision machining, the abrasive particles interact with the workpiece wall surface. By analyzing the material removal of the workpiece round and wall sliding by single abrasive particles, the wear degree of the abrasive particles on the inner surface of the workpiece is discussed, the material removal mechanism of abrasive particles erosion on workpiece wall can be obtained.

2.1 CFD-DEM coupling theoretical model

In solid-liquid two-phase flow, in addition to the transfer of heat, momentum and mass inside the liquid phase, there is also a transfer of heat, momentum and mass between the fluid and the particles. This section mainly describes the coupled theoretical model of computational fluid dynamics (CFD) and discrete element method (DEM).

2.1.1 CFD-DEM resistance model

The model is suitable for handling abrasive particles in two situations:

(1) Abrasive particles of the same size or smaller in volume than the fluid grid unit;

(2) Abrasive particles whose fluid parameters (speed, density, viscosity, etc.) vary substantially constant. The resistance coefficient $C_D$ depends on the Reynolds number $R_e$:

$$ R_e = \frac{\rho v L}{n} $$

$$ C_D = \begin{cases} 
\frac{24}{R_e} & R_e \leq 0.5 \\
24(1.0 + 0.25 R_e^{0.687}) & 0.5 < R_e \leq 1000 \\
0.44 & R_e > 1000 
\end{cases} $$

Where $C_D$ is the resistance coefficient; $R_e$ is the Reynolds number; $\rho$ is the fluid density; $n$ is the viscosity of the fluid; $L$ is the diameter of the abrasive ball; $v$ is the relative velocity between the
abrasive particles and the fluid; \( \alpha \) is the free volume of the CFD grid element. In addition to resistance, the inherent buoyancy of the abrasive particles must also be considered. The formula for calculating buoyancy is:

\[
F_B = \rho g \alpha
\]  

(3)

Generally for Lagrangian coupling, this improved resistance law can be used to consider the effect of abrasive load; And in the Eulerian coupling, the abrasive particle load needs to consider this effect by combining the volume fraction method.

2.1.2 CFD-DEM lift model

(1) Saffman Lift Model

Lifting force is that when the abrasive particles are in a high-speed fluid, the speed gradient causes a pressure difference on the surface of the abrasive particles. Saffman lift can be expressed as:

\[
F_{\text{aff}} = 1.61d_p^2(\mu_f \rho_f)^{1/2}\alpha \left[ (u-v)\omega_p \right]^{1/2}
\]

(4)

Among them, the velocity of the fluid is \( \omega_p = \nabla \cdot u \).

However, this simple model must be very slow at the shear flow rate and satisfy the following conditions:

\[
\begin{align*}
\text{Re}_s & = \frac{|u-v|d_p}{v} < 1 \\
\text{Re}_G & = \frac{|\frac{dy}{dt}d_p^2}{v} < 1 \\
\text{Re}_\Omega & = \frac{|0.5\omega_p - \omega_s|d_p^2}{v} < 1 \\
\varepsilon & = \frac{\text{Re}_G^{1/2}}{\text{Re}_s} > 1
\end{align*}
\]

(5)

Where \( \omega_p \) is the angular velocity of the abrasive particles.

In order to overcome the above constraints, Mei proposed two correlation equations (0.1 < \text{Re}_s < 100):

\[
\frac{F_{\text{aff},\text{mei}}}{F_{\text{aff}}} = \left( 1 - 0.3314\alpha^{1/2} \right) \exp\left( -\frac{\text{Re}_s}{10} \right) + 0.3314\alpha^{1/2}
\]

\[
\text{Re}_s \leq 40
\]

\[
\frac{F_{\text{aff},\text{mei}}}{F_{\text{aff}}} = 0.0524(\alpha \text{Re}_s)^{1/2}
\]

\[
\text{Re}_s > 40
\]

(6)

This correlation equation needs to satisfy a limited shear rate: \( \alpha = 1/2 \text{Re}_s \varepsilon^2 \)

Where 0.005 \( \leq \alpha \leq 0.4 \).

(2) Magnus Lift Model

Magnus lift is the lift due to the spin of the abrasive particles. The relationship between the resistance coefficient of the sphere and the Reynolds number can be expressed as:

\[
\begin{align*}
F_{\text{Mag}} & = 0.125\pi d_p^3 \rho_f \frac{\text{Re}_s}{\text{Re}_\Omega} C_L (0.5\omega_s - \omega_p)(u-v) \\
C_L & = 0.45 + \left( \frac{\text{Re}_G}{\text{Re}_s} - 0.45 \right) \exp(-0.0568 \frac{\text{Re}_G^{0.4}}{\text{Re}_s^{0.3}})
\end{align*}
\]

(7)

This model is still applicable to abrasive particles with Reynolds numbers up to 2000.
2.2 Material Removal Mechanism of Abrasive Particles on Walls Impacted by Different Materials

The workpiece material used in the numerical calculation was stainless steel, in order to obtain abrasive particles with better polishing effect, the abrasive particles of three commonly used materials were selected in this article: SiC, Al₂O₃ and Garnet abrasive. The workpiece and abrasive material parameters were shown in Table 1.

</table>

In order to be able to observe the cutting effect of abrasive particles on the workpiece surface, the numerical simulation was carried out by the impact of different materials on the same workpiece. The equivalent plastic strain cloud diagram of the abrasive particles of different materials on the workpiece is shown in Fig. 1.
As can be found from Fig. 1, the equivalent plastic strain of SiC is greater than the equivalent plastic strain of Al₂O₃ and garnet. Because SiC abrasive grains have the largest microhardness, SiC has the largest plastic deformation ability on the surface of the workpiece, the workpiece has the largest cutting force, and the polishing effect on the workpiece is the best. Therefore, SiC is the best abrasive grain. The abrasive particles used in this study are silicon carbide abrasive particles.

2.3 Study on Material Removal Mechanism of Single Abrasive Particles to Round the Workpiece

Abrasive flow precision machining can effectively round the corners, and the angularity of the variable-diameter pipe parts will directly affect the performance of the workpiece. Abrasive flow precision machining can make the angularity of the workpiece smooth, improve the service life of the parts, improve the stability of the whole component, improve the working efficiency, and the rounding of the inner cavity of the abrasive flow has important application value.

In order to visually observe the effect of the abrasive particles on the workpiece rounding, according to the actual conditions of the abrasive flow precision machining, the incident velocity of the abrasive particle is set at 30 m/s, and the numerical analysis of abrasive flow precision machining collision is carried out at different incident angles. The total time of the numerical analysis is $8 \times 10^{-5}$ s. The movement and velocity changes of the abrasive particle collision workpiece wall are shown in Fig. 2 to Fig. 5.
It can be seen from the analysis of Fig. 2 to Fig. 5 that after the abrasive particle collide with the wall surface, the abrasive particle will rebound in a certain direction, and the speed of the abrasive particle will decrease. This is because when the abrasive particle round the workpiece, the kinetic energy of the abrasive particle is transformed into the internal energy required for the deformation of the workpiece, so that the workpiece is plastically deformed; when the abrasive particle rebound, the abrasive particle velocity starts to increase again, because the reversible plastic deformation begins to recover, which produces reaction force on the abrasive particle and increases the velocity of the abrasive particle; the larger the incident angle, the more the kinetic energy of the abrasive particle loss, and the greater the plastic strain of the workpiece. After a plurality of collisions of the abrasive particle on the workpiece, the surface material of the workpiece is removed, thereby forming a rounding effect on the workpiece.

In order to study the material removal effect of the abrasive particles on the workpiece at different incident angles, five identical abrasive particles were selected to collide the same position of the
workpiece, and 45° and 90° were selected for numerical simulation analysis. The material failure and plastic deformation at different incident angles during the fifth collision were shown in Fig. 6.

(a) When the incident angle is 45°  (b) When the incident angle is 90°

Fig. 6 Material failure and plastic deformation at different incident angles during the fifth collision

It can be seen from Fig. 6 that the plastic strain is not obvious when the incident angle is 45°, but the impact of the abrasive particles has already caused material removal on the workpiece. The part of the workpiece surface removed is the maximum force of the abrasive particles on the workpiece wall. The part is also the angular part of the workpiece, which in turn forms the rounding effect of the abrasive particles on the workpiece. When the incident angle is 90°, the plastic strain of the workpiece is obvious. The groove after the abrasive particles impact is deeper than the incident angle of 45°, but the material is not removed from the workpiece.

2.4 Study on Material Removal Mechanism of Single Abrasive Particle on Wall Surface Sliding

In order to better reveal the material removal mechanism of the abrasive particle collision on the wall surface, numerical analysis of the workpiece and the abrasive particle was carried out. The workpiece wall target was set as a cuboid, the size of the target was 1000μm×500μm×100μm, the diameter of the abrasive particle was 300 meshes, the incident velocity of the abrasive particle was 30 m/s, and there was a slight contact between the abrasive particle and the workpiece wall surface when the abrasive particle collided with the workpiece wall surface. The equivalent effective strain and equivalent effective strain contour maps of the single abrasive particle to wall surface sliding friction are obtained by numerical simulation of abrasive flow precision machining as shown in Fig. 7 and Fig. 8.

Fig.7 Equivalent effective strain diagram of single abrasive particle to wall surface sliding friction
From Fig. 7, it can be seen that in the process of solid-liquid two-phase abrasive flow precision machining, the abrasive particles are subjected to multiple random collisions on the surface of the workpiece under the action of fluid turbulence, and the normal load presses the abrasive particles into the surface of the workpiece. The tangential movement of abrasive particles causes relative sliding between the abrasive particles and the workpiece surface, causing plastic deformation on the surface of the workpiece, causing a scratch on the workpiece, causing plastic wear on the surface of the workpiece. After a number of abrasive particles micro-sliding on the surface of the workpiece, the final realization of the workpiece surface material removal and finishing. It can be seen from Fig. 8 that the position of the abrasive particles extrusion on the workpiece is different, and the amount of plastic deformation is also different. This is because the force of the abrasive particles on the surface of the workpiece is different, and the location where the abrasive particles force on the workpiece is larger, the amount of plastic deformation is larger, the amount of wear on the workpiece is larger, the cutting ability is stronger, and the material removal ability is stronger.

3. Results and Discussion
3.1 Numerical Analysis and Discussion on Precision Machining of Solid-liquid Two-phase Abrasive Flow

The research workpiece is a coaxial fifth-order variable-diameter pipe with symmetrical rotary structure features. The total length of the pipe is 12.7±0.05mm and the diameter is 3.17mm. The numerical analysis of the solid-liquid two-phase abrasive flow precision machining is based on the coupling of CFD-DEM to keep abrasive concentration and abrasive particle size unchanged. The polishing performance of abrasive flow is studied and analyzed by changing the inlet velocity and incident angle of the abrasive particles. CFD-DEM coupling requires high quality of the flow channel model mesh. Therefore, the hexahedral mesh is selected to mesh the fifth-order variable-diameter pipe, and the flow channel model is divided into blocks according to the geometric shape of the model. After meshing, the fifth-order variable-diameter pipe forms 490113 nodes. In this paper, the common index detection of unstructured grid quality is carried out, and there is no negative volume, which indicates that the grid quality is reliable, and the grid quality is greater than 0.3 to meet the simulation requirements. Set the time step in DEM to 5e-7s and turn on Track Collisions. The total time for numerical simulation is 1s. The two-dimensional model of the fifth-order variable-diameter pipe and its flow channel meshing are shown in Fig. 9.
In order to facilitate the analysis of the numerical variation trend of the fifth-order variable-diameter pipe, the fifth-order variable-diameter pipe is divided into 1st-order region, 2nd-order region, 3rd-order region, 4th-order region and 5th-order region. The 1st-order region, 2nd-order region, 3rd-order region, 4th-order region and 5th-order region are respectively set up with 1st-order centerline, 2nd-order centerline, 3rd-order centerline, 4th-order centerline and 5th-order centerline. The centerline of workpiece rotation is defined as the origin of the centerline of each order region. The centerline of workpiece rotation is positive above, the centerline of workpiece rotation is negative below. The abrasive inlet is defined as the origin of the workpiece rotation centerline. The wall surface in the positive direction of Y axis is defined as the upper wall surface, while the wall surface in the negative direction of Y axis is the lower wall surface. The incident angle of abrasive is set to $\alpha$, the regional division of the flow channel of the two-dimensional model of the fifth-order variable-diameter pipe is shown in Fig. 10.

Fig. 10 Schematic diagram of the regional division of the flow channel in the two-dimensional model of the fifth-order variable-diameter pipe

### 3.1.1 Numerical Simulation Analysis of Precision Machining of Inlet Velocity on Fifth-order Variable-diameter Pipe

(1) Coupled Field Analysis of Fluid Dynamic Pressure and Total Energy of Abrasive Particles in Fifth-order Variable-diameter Pipe Machined at Different Inlet Velocities

The abrasive concentration was set to 10%, the abrasive particle size was 300 mesh (48μm), the inlet velocity was 30m/s and 45m/s for CFD-DEM coupling numerical simulation analysis. Cloud dynamic pressure and total particle energy cloud diagrams of CFD-DEM coupling fields at different
inlet velocities were obtained, as shown in Fig. 11.

![Image of coupled field nephograms of fluid dynamic pressure and total energy of abrasive particles at different inlet velocities]

(a) When the inlet velocity is 30m/s

(b) When the inlet velocity is 45m/s

Fig. 11 Coupled field nephograms of fluid dynamic pressure and total energy of abrasive particles at different inlet velocities

It can be seen from Fig. 11 that the dynamic pressure increases stepwise when the abrasive flow flows from the 1st-order region to the 3rd-order region. This is because the dynamic pressure is increased by the aperture reduction, the more intense the abrasive movement, and the increased chance of wall surface collision. Thereby, the polishing effect of the abrasive flow on the small aperture can be improved. The 3rd-order region has the highest dynamic pressure and the best polishing effect on the 3rd-order region. When the abrasive flows from the 3rd-order region to the 5th-order region, due to the influence of the inertia of abrasive, the dynamic pressure at the intersection of the large hole and the small hole still keeps relatively high. With the abrasive flow out, the dynamic pressure decreases gradually. Because of the enlargement of the aperture, the abrasive rarely reaches the workpiece near the wall surface, and the abrasive directly flows out of the workpiece from the fluid center, so the dynamic pressure near the wall surface is the lowest value, which is not conducive to the finishing of the 4th-order region and the 5th-order region. In order to improve the uniformity of abrasive flow precision machining workpiece, the workpiece can be processed in two directions.

(2) Coupled Field Analysis of Shear Force on Fluid Wall of the Fifth-order Variable-diameter Pipe Machined at Different Inlet Velocities

Since the abrasive is a viscous liquid, it will have a certain viscous effect on the wall surface, and the abrasive is similar to "adsorption" on the wall surface of the workpiece. When the abrasive particles in the fluid leave the wall surface of the workpiece, it is necessary to overcome the viscous resistance and the adsorption force between the abrasive particles in the fluid and the wall surface of the workpiece. At this time, a certain shear force is formed on the wall surface of the workpiece, and the shear force is greater than the ultimate stress of the workpiece surface material, the workpiece material will fall off the surface of the workpiece. Under the same numerical simulation conditions, the coupled field nephograms of fluid wall surface shear force under different inlet velocity conditions is obtained, as shown in Fig. 12.
Fig. 12 Coupled field nephograms of fluid wall surface shear force under different inlet velocity conditions.

It can be seen from the color change of each order region in Fig. 12 that the shear force of the fluid wall surface of the 1st-order region to the 3rd-order region is gradually increasing. Because in this process, the pore diameter is gradually smaller, which makes the pressure of the abrasive on the wall gradually increase, and the wall shear force is also gradually increased. In the 3rd-order region, the wall shear force is the largest and the polishing effect is the best. When the abrasive flows into the 5th-order region from the 3rd-order region, the wall surface shear force decreases stepwise, because the aperture becomes larger, the pressure of the abrasive flow to the wall surface decreases, and in the 4th-order region, the wall surface shear force near the 3rd-order region is relatively small, and the middle and rear end wall surface shear force tends to increase, which is beneficial to the finishing of the middle and rear end in the 4th-order region, and the polishing effect on the beginning of the 4th-order region and the 5th-order region is poor.

3.1.2 Numerical Simulation Analysis of Precision Machining of Fifth-order Variable-diameter Pipe by Incident Angle

Since the above processing technology is not conducive to the polishing uniformity of each step of the fifth-order variable-diameter pipe, in order to improve the polishing effect of each step of the workpiece, the abrasive flow precision machining for the workpiece at different incident angles is proposed, and the direction of the incident angle of the abrasive is defined as shown in Fig. 10.

(1) Coupled Field Analysis of Fluid Velocity and Abrasive Particles Velocity of Fifth-order Variable-diameter Pipe Machined at Different Incident Angles

When the abrasive concentration is 10%, the abrasive particle size is 300 meshes (48μm) and the inlet velocity is 45 m/s, the incident angles were selected as 0° and 15° for coupled numerical simulation analysis. The fluid velocity and the abrasive particles velocity nephograms for the different incident angles at the coupled field are shown in Fig.13.
It can be seen from Fig. 13 that the fluid velocity distribution changes obviously when the incident angle is changed; the larger the incident angle is, the more obvious the fluid velocity distribution changes. When the incident angle is 0°, the fluid velocity distribution is symmetric about the workpiece rotation centerline, but when the incident angle is greater than 0°, the fluid velocity is no longer symmetrical about the centerline of the workpiece rotation, and the fluid velocity at the lower end of the centerline of the workpiece is greater than that at the upper end, but the fluid velocity at the near wall surface of the lower end of the centerline of the workpiece in the 4th-order region and 5th-order regions is significantly improved. The polishing effect of the lower end wall surface of the workpiece rotation centerline is better than that of the upper end wall surface. Similarly, 3rd-order region has the greatest fluid velocity and uniform fluid velocity distribution, so the polishing effect is best for the 3rd-order region. The larger the incident angle is, the more times the abrasive particles collide with the workpiece wall surface, so that the polishing effect of the lower wall surface of the 4th-order region and the 5th-order region can be improved to some extent.

(2) Coupled Field Analysis of Fluid Dynamic Pressure and Total Energy of Abrasive Particles of Fifth-order Variable-diameter Pipe Machined at Different Incident Angles

Under the same numerical simulation conditions, the coupled field nephograms of fluid dynamic pressure and total energy of abrasive particles at different incident angles are obtained, as shown in Fig. 14.
It can be seen from Fig. 14 that when the incident angle is $0^\circ$, the fluid dynamic pressure distribution is symmetric about the workpiece rotation centerline, and when the incident angle is greater than $0^\circ$, the fluid dynamic pressure is no longer symmetric about the workpiece rotation centerline, but the fluid dynamic pressure near the lower wall of the 4th-order region and the 5th-order region is obviously improved. The polishing effect of the lower end wall surface of the workpiece rotation centerline is better than that of the upper end wall surface, and the upper wall surface polishing effect is worse. Similarly, the dynamic pressure of the 3rd-order region is the largest, and the fluid dynamic pressure distribution is relatively uniform, so the polishing effect is best for the 3rd-order region. The total energy of the abrasive particles increases first and then decreases. The total energy of the abrasive particles reaches the maximum at the junction of the 3rd-order region and the 4th-order region, and the larger the incident angle, the more the number of collisions between the abrasive particles and the lower wall surface of the workpiece, thus, the polishing effect of the lower wall surface of the 4th-order region and the 5th-order region is improved to a certain extent, and the polishing effect of upper wall surface is poor.

(3) Distribution of Abrasive Particles in the Fifth-order Variable-diameter Pipe at Different Times When the Incident Angle is $0^\circ$ and $15^\circ$

The movement of the abrasive particles at different times in the fifth-order variable-diameter pipe was analyzed. The numerical simulation was carried out by selecting the incident angles of $0^\circ$ and $15^\circ$, and the distribution of the abrasive particles at different times was obtained, as shown in Fig. 15 and Fig. 16.

![Abrasive particles velocity](image)

(a) Machining time is $6e^{-5}s$

(b) Machining time is $1.1e^{-4}s$

(c) Machining time is $1.4e^{-4}s$

(d) Machining time is $1.6e^{-4}s$

(e) Machining time is $1.7e^{-4}s$

Fig. 15 The movement of the abrasive particles in the fifth-order variable-diameter pipe when the incident angle is $0^\circ$
(a) Machining time is $6\times 10^{-5}$s

(b) Machining time is $1.2\times 10^{-4}$s

(c) Machining time is $1.5\times 10^{-4}$s

(d) Machining time is $1.7\times 10^{-4}$s

(e) Machining time is $1.8\times 10^{-4}$s

Fig. 16 The movement of the abrasive particles in the fifth-order variable-diameter when the incident angle is $15^\circ$

From the comparison of Fig. 15 and Fig. 16, it can be seen that the distribution of the abrasive particles when the incident angles are $0^\circ$ and $15^\circ$, respectively, the time required for the abrasive particles to flow out of the workpiece when the incident angle is $0^\circ$ is less than that when the incident angle is $15^\circ$. It means that the abrasive particles collide with the wall surface for a long time when the incident angle is $15^\circ$, which is beneficial to the polishing of the workpiece. When the incident angle is $0^\circ$, the distribution of the abrasive particles is uniform. When the incident angle is $15^\circ$, the distribution of the abrasive particles is not uniform, and it is concluded that the polishing is uniform when the incident angle is $0^\circ$.

3.2 Test Analysis and Discussion on Abrasive Flow Precision Machining of Fifth-order Variable-diameter Pipe

Many scholars have researched some new methods to improve the surface quality of the workpieces being processed. L. N. Lopez and other scholars proposed the use of newly developed utility programs in the preparation stage for the processing of advanced high-strength steel (AHSS) forming tools, and the use of CAM software to write CNC programs to improve the finishing [27]. Zou L and other scholars verified the feasibility of the flexible grinding method for precision machining of TiAl-based alloys from the aspects of material removal rate, abrasive wear, surface roughness and residual stress [28]. Gou L and other scholars used a UV-curing resin plate grinding process to improve the surface roughness of the workpiece by $12\%$ and reduce the material removal rate by $25\%$ [29]. Wang TT and other scholars have developed a new atomic force microscope and studied the effects of abrasive media and process parameters on new abrasive particle flow processing [30]. Wei HB and other scholars have proposed a new abrasive particle flow machining material removal prediction model, which can predict material removal based on the change of the contour height and the mass change of the material [31]. In order to verify the effectiveness of abrasive flow polishing
variable-caliber pipe parts, the abrasive flow polishing process parameters were selected with an inlet speed of 45 m/s, an abrasive concentration of 10%, and an abrasive particle size of 800 mesh. Comparative tests of unidirectional and bidirectional abrasive flow polishing were performed.

3.2.1 Surface Roughness Analysis of Abrasive Flow Precision Machining of Fifth-order Variable-diameter Pipe

A fifth-order variable-caliber pipe made of stainless steel 304 was selected as the abrasive flow polishing test object. The Physical diagram of the fifth-order variable-diameter pipe after cutting is shown in Fig. 17.

![Fig. 17 Physical diagram of the fifth-order variable-diameter pipe after cutting](image)

In order to analyze the internal surface roughness of the workpiece before and after the abrasive flow polishing, a Mahr stylus gauge is selected for surface roughness detection on the inner surface of the fifth-order variable caliber tube. The inner surface of the fifth-order variable-caliber pipe is contact-tested by a probe. The surface roughness Ra value of the fifth-order variable-caliber pipe is shown in Table 2.

It can be seen from Table 2 that the surface roughness after one-way and two-way abrasive flow precision machining is significantly reduced, and the surface quality of the workpiece is obviously improved. Through the comparison and analysis each order region of one-way abrasive flow precision machining, the inner surface roughness value is 5th-order region > 4th-order region > 1st-order region > 2nd-order region > 3rd-order region. This shows that the size of the aperture will affect the inner surface roughness value. The smaller the aperture, the larger the amount of material removed, and the better the polishing effect on the workpiece, but the polishing of each order region is uneven, and the two-way abrasive flow precision machining improves the unevenness of polishing. In order to visually observe the trend of the original, one-way and two-way surface roughness values, a surface roughness line chart of each order region as shown in Fig. 18 is drawn.
From Fig. 18, it can be seen that the surface roughness of each order region after one-way and two-way abrasive flow precision machining is obviously reduced. The surface roughness of the 4th-order region and the 5th-order region after one-way abrasive flow precision machining was larger, and the polishing effect is not good. The inner surface roughness value of each order region after two-way abrasive flow precision machining is relatively flat, which is beneficial to improve the inner surface quality of workpiece.

3.2.2 Surface Morphology Analysis of Abrasive Flow Precision Machining of Fifth-order Variable-diameter Pipe

In order to better analyze the surface quality of abrasive flow precision machining the fifth-order variable-diameter pipe, scanning electron microscopy (SEM) is used to detect the surface morphology of the fifth-order variable-diameter pipe before and after one-way abrasive flow precision machining. The surface morphology of the fifth-order variable-diameter pipe before and after abrasive flow precision machining is obtained as shown in Fig. 19 and Fig. 20.
It can be known from Fig. 19 and Fig. 20 that a large number of uneven spots and burrs are distributed on the inner surface of the fifth-order variable-aperture pipe workpiece before the abrasive flow polishing, and the distribution is relatively disordered and the surface quality is poor. After polishing with unidirectional abrasive flow, a lot of striped scratches appeared on the surface of the workpiece, and the spots and burrs on the workpiece surface basically disappeared, the surface was smoother, and the surface quality is significantly improved. A comparative analysis of each step region of the fifth-order variable-caliber pipe can be seen: the smoothness of the 1st-order region and the 2nd-order region is better, and the surface quality is significantly improved. The 3rd-order region has the best finish and the best polishing effect. A small amount of glitches in the 4th-order region, and the surface quality of the 5th-order region is the worst. The surface roughness Ra value of each area of the fifth-order variable-caliber tube after precision machining by the abrasive flow is: 5th-order region > 4th-order region > 1st-order region > 2nd-order region > 3rd-order region. The detection results are consistent with the numerical simulation results, which verifies the accuracy of the numerical simulation. By examining the surface morphology after polishing with bidirectional abrasive flow, and the surface morphology diagram shown in Fig. 21 is obtained.
It can be seen from Fig. 21 that the stripe-like scratches on the surface of the fifth-order variable-aperture pipe are more clear after the bidirectional abrasive flow polishing, the burr on the surface of the workpiece disappears, the surface is smoother, and the surface quality is significantly improved. A comparative analysis of each order region shows that the processing effect of the 1st-order region and the 5th-order region is basically close; the surface quality of the 2nd-order region and the 4th-order region are also very close; the inner surface of the 3rd-order region is the smoothest and has the best polishing effect. Compared with the effect of unidirectional abrasive flow polishing, the internal surface quality of each step region after polishing by bidirectional abrasive flow is significantly improved. Therefore, polishing the five-step variable-caliber pipe parts with bidirectional abrasive flow can make the processing more uniform, which is more conducive to improving the quality of the inner surface of the workpiece.

4. Conclusion

(1) During the precision machining of solid-liquid two-phase abrasive flow, the surface finishing of the workpiece is formed by the interaction between the abrasive particles and the wall surface. After the abrasive particles collide with the wall surface, the abrasive particles will rebound in a certain direction, and the kinetic energy of the abrasive particles is converted into the internal energy required for the deformation of the workpiece, so that the surface of the workpiece is plastically deformed; the larger the incident angle, the more kinetic energy of abrasive particles loss, the greater the plastic strain of the workpiece; after multiple collisions of the abrasive particles on the workpiece, the normal load presses the abrasive particles into the surface of the workpiece, and the tangential movement of the abrasive particles causes the abrasive particles to slide relative to the surface, causing the surface of the workpiece to occur plastic deformation, a scratch on the workpiece, plastic wear on the workpiece surface, when the shear force is greater than the ultimate stress of the workpiece surface material, and after several times of micro-sliding friction on the surface of the workpiece, the abrasive particles eventually achieve the material removal and finishing of the workpiece surface.

(2) Through the numerical analysis of the solid-liquid two-phase abrasive flow precision machining, it is found that the dynamic pressure increases when the abrasive particles flow into the small aperture from the large aperture, and the dynamic pressure decreases when the abrasive particles flow into the large aperture from the small aperture; the greater the dynamic pressure is, the more violent the abrasive particles movement is, the more chance the abrasive particles collide with the wall surface; the dynamic pressure data at the rotation centerline of the fifth-order variable-diameter pipe is 3rd-order region>4th-order region>5th-order region>2nd-order region>1st-order region, the finishing effect of the 3rd-order region is the best. The wall surface shear force at the center of the fluid is 0, and only the shear force is generated at the wall surface. In the 5th-order region, the wall surface shear force is the smallest, the number of collisions between the abrasive particles and the 5th-order region...
wall surface is small, the amount of material removal on the workpiece surface is less, and the polishing effect in the 5th-order region is the worst.

(3) Changing the incident angle can change the velocity distribution of the abrasive flow. The larger the incident angle, the more obvious the change of the fluid velocity distribution. When the incident angle is 0°, the fluid velocity distribution is symmetric about the centerline of the workpiece rotation, which can effectively improve the polishing effect of the 4th-order region and 5th-order regions; when the incident angle is greater than 0°, the fluid velocity is no longer symmetrical about the centerline of the workpiece rotation, and the fluid velocity at the lower end of the workpiece rotation centerline is greater than that at the upper end; when the incident angle is 90°, the workpiece has obvious plastic deformation; the larger the incident angle, the more collisions between the abrasive particles and the workpiece wall surface, the more favorable the abrasive particles to remove the workpiece material, the more favorable the precision processing effect of the abrasive flow.

(4) Before abrasive flow precision machining, the inner surface of the fifth-order variable-diameter pipe workpiece is distributed with many uneven spots and burrs, which are disorderly and poor in surface quality. After abrasive flow precision machining, the streaky scratches on the surface of the fifth-order variable-diameter pipe workpiece are clearer, the spots and burrs on the workpiece surface disappear, the surface is smoother and the surface quality is obviously improved. The surface roughness of each order region after precision machining by abrasive flow is obviously improved, and the surface finishing of the 3rd-order region is the best. The two-way machining can obtain a uniform surface better than the one-way machining, and can obtain better surface quality.
